Abstract
Imperfection sensitivity properties are derived for finite dimensional elastic conservative systems exhibiting hill-top branching at which arbitrary many bifurcation points coincide with a limit point. The critical load at a hill-top branching point is demonstrated to be insensitive to initial imperfections when all the bifurcation points are individually symmetric. Therefore, it is not dangerous to design a frame or truss so that many members buckle simultaneously at the limit point, although the notion of the danger of optimization by compound bifurcation is widespread.

Keywords Coincident buckling; Hill-top branching; Imperfection sensitivity; Member buckling; Symmetric bifurcation

1 Introduction
The simultaneous buckling was studied in association with optimization. The principle of simultaneous mode design states, “A given form will be optimum if all failure modes which can possibly intersect occur simultaneously (Spunt, 1971).” The danger of naive optimization without due regard to imperfection sensitivity and the erosion of optimization by compound branching were suggested (Thompson and Supple, 1973). Various kinds of structures were found highly imperfection-sensitive when two or more bifurcation points are nearly or strictly coincident, and are subjected to interaction of buckling modes, such as local and global modes (Hutchinson and Amazigo, 1967; Koiter and Kuiken, 1971; Thompson and Lewis, 1972; Tvergaard, 1973). Thompson and Hunt (1974) suggested extreme enhancement of imperfection sensitivity due to modal interaction as a result of optimization; imperfection sensitivity of coincident critical points was studied thereafter (Thompson and Hunt, 1984; Hunt, 1986).

Yet such severe enhancement of imperfection sensitivity is absent for another kind of coincident critical points. A nearly coincident pair of a bifurcation point and a limit

\[1\]
This paper has appeared in: Int. J. Solids and Struct., Vol. 43, No. 16, pp. 4704-4719, 2006.
point of loading parameter was found in (a) numerical simulation of a long tensile steel specimen undergoing plastic instability (Needleman, 1972), and (b) mechanical instability of stressed atomic crystal lattices (Thompson and Schorrock, 1975). Such a pair of points was approximated by a hill-top branching (bifurcation) point, at which the pair of points coincide strictly. This hill-top point was shown to enjoy locally piecewise linear imperfection sensitivity (Thompson and Schorrock, 1975; Thompson, 1982; Ikeda et al., 2002; Okazawa et al., 2002), which is less severe than the two-thirds power-law for a simple pitchfork bifurcation point. A piecewise linear relationship was also observed for other hill-top branching points that occur as the coincidence of

(i) an asymmetric bifurcation point and a limit point (Ohsaki, 2003), and
(ii) a limit point and a double bifurcation point studied by a group-theoretic approach (Ikeda et al., 2005).

Ohsaki (2000) optimized shallow trusses under constraints on nonlinear buckling and found that the optimum solution usually has a hill-top branching point, which is not sensitive to imperfections. Thus the optimization for nonlinear buckling does not always produce a dangerous structure.

It is noteworthy that, for a pin-jointed truss, member buckling can occur almost independently from global buckling (Peek and Triantafyllidis, 1992). Therefore, it is possible to create a hill-top branching point at which arbitrary many symmetric bifurcation points can exist at a limit point; i.e. many members buckle simultaneously with global buckling.

The basic framework to deal with coincident critical points can be found in the static perturbation method (Supple, 1967, 1968; Thompson and Hunt, 1973, 1984; Godoy, 1999); in this framework, compound bifurcations were studied in detail (Hunt, 1981). Critical points can be classified by investigating the linear, quadratic, cubic, quartic, ... terms of the total potential energy (Thompson and Hunt, 1973). The interaction between bifurcation modes is classified into third-order and fourth-order interactions; the third-order interaction exists if one of the bifurcation modes is asymmetric. The maximum load of an imperfect symmetric system is reduced if the forth-order cross-term is negative (Thompson and Hunt, 1984).

In this paper, imperfection sensitivity of a hill-top branching point with many symmetric bifurcation points is investigated. This point is actually created for a pin-jointed truss with simultaneously buckling members. The bifurcation modes are individually symmetric among themselves, but some modes have infinitesimally small third-order interaction. The symmetry conditions with respect to bifurcation modes and limit-point-type mode are relaxed by ignoring such interaction to account for practical situation of member buckling at the limit point.

2 Illustrative example of a hill-top branching.

We start with a simple illustrative example: a 2-bar truss as shown in Fig. 1, where $H = 100\, \text{mm}$ and $L = 1000\, \text{mm}$. The members are connected to the nodes by
Fig. 1: A 2-bar pin-jointed truss.

Fig. 2: Relation between the cross-sectional area and critical load ratio of the 2-bar truss.

pin joints. Each member is divided into four beam elements to implement member buckling. Green’s strain is used for representing geometrically nonlinear strain-displacement relation. In the following, the units of length and force are mm and kN, respectively.

Maple 9, a symbolic computation software, is used for the differentiation of the total potential energy with respect to displacements, imperfection parameters, etc. The equilibrium paths are traced by a displacement increment method with sufficiently small increments, and it has been confirmed that unbalanced loads at every incremental step are very small.

Let $I$ and $A$, respectively, denote the second moment of area and the cross-sectional area of the members which have a $D \times D$ solid square cross-section; i.e. $I = D^4/12 = A^2/12$. The elastic modulus is denoted by $E$. The vertical load is defined by a unit load $P$ and load factor $\Lambda$ as $\Lambda P$, and $\Lambda$ is increased to find the critical load factor $\Lambda^c$ where the lowest eigenvalue of the tangent stiffness matrix vanishes. Fig. 2 shows the variation of the critical load ratio $\Lambda^c P/(EA)$ plotted against $A$. For a large value of $A$, the critical point is governed by a limit point. On the other hand, if $A$ is small, member buckling occurs before reaching the limit point.
Consider an optimization problem of maximizing $\Lambda^cP/(EA)$ that is conceived as the critical load for the unit cost. It is seen from Fig. 2 that $\Lambda^cP/(EA)$ increases as $A$ is increased from 0. At $A = A^* \simeq 3984.0$, bifurcation points exist at the limit point, which is called a hill-top branching point. For $A \geq A^*$, $P^c/(EA)$ is constant; accordingly, the structure with $A = A^*$ can be regarded as the optimal solution that achieves the maximum $\Lambda^cP/(EA)$ with the smallest $A$. As we have seen, structural optimization entails hill-top branching.

Fig. 3 shows the relation between $\Delta P$ and the vertical displacement $v$ at the center node for $A = 3000.0$ that has a double bifurcation point before reaching a limit point, where $E = 1$ for simplicity. The eigenmodes $\hat{p}_1$ and $\hat{p}_2$ for zero eigenvalues at the double bifurcation point are shown in Fig. 4. Notice that only member buckling occurs in both $\hat{p}_1$ and $\hat{p}_2$. Let $U^c$ denote the nodal displacement vector at the double bifurcation point. Deformation in the vicinity of $U^c$ is defined as

$$U = U^c + q_1\hat{p}_1 + q_2\hat{p}_2$$ \hspace{1cm} (1) 

where $q_1$ and $q_2$ are called generalized coordinates. The contour map of the total potential energy $V$ scaled as $10000(V + 12.2896)$ is plotted in Fig. 5 with respect to $q_1$ and $q_2$. Since $\hat{p}_1$ is antisymmetric with respect to the vertical reflection axis of the
truss, $V$ is a symmetric (even) function of $q_1$. Although the deformations defined by $U^c + q_2 \hat{p}_2$ and $U^c - q_2 \hat{p}_2$ have different properties, $V$ is almost symmetric with respect to $q_2$ as can be seen from Fig. 5, because only member buckling occurs in $\hat{p}_2$ and is not influential on nodal displacements.

Fig. 6 shows the relation between $\Lambda P$ and the vertical displacement $v$ at the center.
Fig. 7: Relation between vertical displacement and eigenvalues for $A = A^*$.  

![Graph of Eigenvalues vs. Displacement](image)

Fig. 8: Orthogonal eigenmodes corresponding to the three zero eigenvalues at the hill-top point.

1st mode $\hat{p}_1$

2nd mode $\hat{p}_2$

3rd mode $\hat{p}_3$

It is confirmed from Fig. 6 that a limit point is reached as $v$ is increased. The eigenvalues of the tangent stiffness matrix are plotted in Fig. 7. It should be noted that the three lowest eigenvalues do not coincide before reaching the hill-top point, where they simultaneously vanish. The eigenmodes corresponding to the three eigenvalues are as shown in Fig. 8. The eigenmode $\hat{p}_2$ corresponds to a symmetric bifurcation due to member buckling without displacement at the center node, and $\hat{p}_1$ and $\hat{p}_3$ are the mixture of limit point mode and bifurcation mode due to member buckling. Thus the coincidence of a limit point and bifurcation points incurs the mixing of eigenmodes.

Since any linear combination of critical modes at a coincident critical point is also a critical mode, it is possible to extract the limit point mode and the bifurcation mode due to member buckling from the critical modes mixed in this manner. From the general theory of elastic stability (Thompson and Hunt, 1973), the limit point mode can be obtained from the incremental displacement along the fundamental equilibrium
1st mode \( p_1 \)

2nd mode \( p_2 = \dot{p}_2 \)

3rd mode \( p_3 \) (limit point mode)

Fig. 9: Non-orthogonal eigenmodes corresponding to the three zero eigenvalues at the hill-top point.

path at the limit point, which turns out to be the 3rd mode \( p_3 \) in Fig. 9. The bifurcation mode \( p_1 \) in Fig. 9 is obtained as a pertinent linear combination of \( \dot{p}_1 \) and \( p_3 \) in Fig. 8 so that the vertical displacement of the center node vanishes.

The third-order differential coefficients \( V_{ijk} \) of the total potential energy in the directions of modes \( i, j, k (= 1, 2, 3) \) in Fig. 9 are obtained as

\[
\begin{align*}
V_{111} &= 2.8454 \times 10^{-10}, \quad V_{112} = 5.0485 \times 10^{-15}, \quad V_{113} = 7.8384 \times 10^{-5}, \\
V_{122} &= -2.6232 \times 10^{-10}, \quad V_{123} = 1.2865 \times 10^{-11}, \quad V_{133} = 2.8728 \times 10^{-13}, \\
V_{222} &= 2.6394 \times 10^{-15}, \quad V_{223} = 7.8385 \times 10^{-5}, \quad V_{233} = 1.2026 \times 10^{-12}, \\
V_{333} &= 7.4097 \times 10^{-5}
\end{align*}
\]

Since the loaded center node moves in \( p_3 \), and \( V_{333} \) has larger value than \( V_{111} \) and \( V_{222} \), \( p_3 \) can be confirmed to be a limit point mode. \( p_2 \) is a symmetric bifurcation mode, because it is antisymmetric with respect to \( y \)-axis. \( p_1 \) is an almost symmetric (slightly asymmetric) mode, because \( V_{111} \) has a very small value, although the mode shape is not antisymmetric. The symmetricity may be further investigated by computing the 5th and higher differential coefficients of \( V \). In the following sections, general formulations are presented for imperfection sensitivity for a hill-top branching point with arbitrary many symmetric bifurcation points.

3 Hill-top branching at the perfect system.

We next consider a general case of finite dimensional geometrically nonlinear structure, of which the deformation is described by the nodal displacement vector \( U = (U_1, \ldots, U_n) \), where \( n \) is the number of degrees of freedom. We assume the existence of the total potential energy \( \bar{V}(U, \Lambda) \) that is a smooth function of \( U \) and loading parameter \( \Lambda \).
Denote by \( H \) the Hessian of \( \bar{V} \) with respect to \( U \), which is called tangent stiffness matrix. The eigenvalue problem of \( H \) is formulated as

\[
H \hat{p}_i = e_i \hat{p}_i, \quad (i = 1, \ldots, n)
\]

where \( e_i \) is the \( i \)th lowest eigenvalue \( (e_i \leq e_{i+1}) \), and \( \hat{p}_i \) is the associated eigenvector normalized by \( \hat{p}_i^\top \hat{p}_i = 1 \) \((i = 1, \ldots, n)\), where \( (\cdot)^\top \) denotes the transpose of a vector.

Consider a case where \( m - 1 \) bifurcation points exist at a limit point; i.e. the critical point is a hill-top branching point with \( m \) lowest eigenvalues vanishing simultaneously.

To separate the bifurcation modes and the limit point mode, the increment of \( U \) at the limit point along the fundamental equilibrium path is used for defining the limit point mode \( p_m \) as demonstrated in the previous section. The bifurcation modes \( p_i \) \((i = 1, \ldots, m-1)\) are obtained by removing the component of \( p_m \) from \( \hat{p}_i \) as

\[
p_i = \hat{p}_i + c_i p_m, \quad (i = 1, \ldots, m-1)
\]

where the coefficient \( c_i \) is computed from

\[
p_m^\top (\hat{p}_i + c_i p_m) = 0, \quad (i = 1, \ldots, m-1)
\]

The generalized coordinate \( q_j \) in the direction of \( p_j \) is defined by the transformation

\[
U = U^c + \sum_{j=1}^{n} q_j p_j
\]

where \( U^c \) is the displacement vector at the critical point.

Denote by \( q_1, \ldots, q_{m-1} \) the generalized coordinates in the direction of bifurcation modes measured from the hill-top point, and by \( q_m \) that in the direction of limit-point mode. Then \( q_1, \ldots, q_m \) serve as active coordinates and \( q_{m+1}, \ldots, q_n \) as passive coordinates. The increment of the loading parameter from the hill-top point is denoted by \( \lambda \).

The total potential energy is defined as a function of \( q = (q_1, \ldots, q_n) \) and \( \lambda \) and is written as \( V(q, \lambda) \). Differentiation with respect to \( q_i \) is indicated by a subscript \( i \). The equilibrium equations are written as

\[
V_i = 0, \quad (i = 1, \ldots, n)
\]

Since \( m \) lowest eigenvalues \( e_i \) \((i = 1, \ldots, m)\) vanish at the hill-top point, the following relations hold:

\[
V_{ij} = 0, \quad (i, j = 1, \ldots, m)
\]

For the modes \( p_i \) \((i = m + 1, \ldots, n)\) higher than \( m \), orthogonality conditions

\[
p_i^\top p_j = 0, \quad (i, j = m + 1, \ldots, n; \ i \neq j)
\]
should be satisfied so that $V_{ij}$ is diagonalized such that

$$V_{ij} = 0, \quad (i, j = m + 1, \ldots, n; \ i \neq j)$$  \hspace{1cm} (10)

$$V_{ij} = V_{ji} = 0, \quad (i = 1, \ldots, m; \ j = m + 1, \ldots, n)$$  \hspace{1cm} (11)

Note that the orthogonality among the eigenvectors $p_i$ ($i = 1, \ldots, m$) need not be satisfied, because, for multiple eigenvalues, any linear combination of the eigenvectors is also an eigenvector.

From the conditions of limit point and bifurcation points,

$$V_i' = 0, \quad (i = 1, \ldots, m - 1)$$  \hspace{1cm} (12)

$$V_m' \neq 0$$  \hspace{1cm} (13)

are to be satisfied, where $(\cdot)'$ indicates differentiation with respect to $\lambda$.

### 4 Imperfection sensitivity analysis at hill-top point.

We move on to consider a critical point of an imperfect system. Let $\varepsilon$ denote the imperfection parameter. The total potential energy of an imperfect system, which is a function of $n + 2$ variables $\lambda$, $q_1$, $\ldots$, $q_n$ and $\varepsilon$, is written as $V(q, \lambda, \varepsilon)$. Since $n$ equilibrium equations (7) should be satisfied for $n + 2$ variables, an equilibrium state is to be determined by specifying two variables; say, e.g. $\varepsilon$ and $\lambda$.

Suppose without loss of generality that the imperfection is influential both on the bifurcation modes and the limit point mode; i.e. $q_1$ and $q_m$ are assumed to have nonzero values at a critical point of the imperfect system. Then $q_1$ and $q_m$ can be taken as two independent parameters, and the following relations hold:

$$q_{1m} = q_{m1} = 0, \quad q_{11} = q_{mm} = 1$$  \hspace{1cm} (14)

where $q_{ij}$ denote differentiation of $q_i$ with respect to $q_j$.

Differentiating the $i$th equilibrium equation $V_i = 0$ in (7) with respect to $q_s$ ($s = 1$ or $m$) leads to

$$\sum_{j=1}^{n} V_{ij} q_{js} + V_i' \lambda_s + \dot{V}_i \varepsilon_s = 0, \quad (i = 1, \ldots, n; \ s = 1 \text{ or } m)$$  \hspace{1cm} (15)

where a dot denotes differentiation with respect to $\varepsilon$.

For $i = 1$ or $m$, incorporating (8), (10), (11) and (12) into (15) results in

$$\lambda_s = \varepsilon_s = 0, \quad (s = 1 \text{ or } m)$$  \hspace{1cm} (16)

For $i = m + 1, \ldots, n$, incorporating (16) into (15) results in

$$q_{is} = 0, \quad (s = 1 \text{ or } m)$$  \hspace{1cm} (17)
Therefore, the differential coefficients of the passive coordinates $q_i$ ($i = m + 1, \ldots, n$) vanish, and, in turn, the passive coordinates have lower order than the two active coordinates $q_1$ and $q_m$; i.e.

$$|q_i| \ll |q_s|, \quad (i = m + 1, \ldots, n; \ s = 1 \ or \ m) \quad (18)$$

By further differentiating (15) with respect to $q_t$ ($t = 1 \ or \ m$) and using (8), (10), (11), (16) and (17), we obtain

$$V_{ii}q_{ist} + \sum_{j=1}^{m} \sum_{k=1}^{m} V_{ijk} q_{js} q_{kt} + V_i' \lambda_{st} + \dot{V}_i \varepsilon_{st} = 0, \quad (s, t = 1, m; \ i = 1, \ldots, n) \quad (19)$$

Letting $(i, s, t) = (1, 1, m)$ in (19),

$$V_{11m} + \dot{V}_1 \varepsilon_{1m} = 0 \quad (20)$$

is obtained; i.e. $\varepsilon_{1m} \neq 0$ and $\varepsilon$ has the quadratic order of the two active coordinates. Similarly, if we set $(i, s, t) = (m, m, m)$ in (19),

$$V_{mmm} + V_m' \lambda_{mm} = 0 \quad (21)$$

is obtained; i.e. $\lambda_{mm} \neq 0$ and $\lambda$ also has the quadratic order. Finally, it is easily observed from (19) for $i > m$ that $q_{ist} \neq 0$ is satisfied; i.e. the passive coordinates are also quadratic function of the active coordinates. Note that these relations are satisfied if at least one bifurcation point exists at a limit point.

Hence, the following relations hold:

$$\begin{align*}
|q_i| &= O(\varepsilon^{1/2}), \quad (i = 1, \ldots, m) \\
|q_i| &= O(\varepsilon), \quad (i = m + 1, \ldots, n) \\
|\lambda| &= O(\varepsilon)
\end{align*} \quad (22)$$

i.e. the load factor $\lambda$ has the linear order of the imperfection parameter $\varepsilon$.

As the objective of this paper, quantitative imperfection sensitivity analysis is conducted by using the third-order systems along with the static perturbation procedure by Thompson (1982). In the following, all variables are evaluated at the hill-top point.

Assumptions on the derivatives of $V$ employed are

- All $m - 1$ bifurcation points are symmetric, and $V$ is individually symmetric (Thompson and Hunt, 1984) up to the third-order terms in the subspace of the bifurcation modes; i.e.

$$V_{ijk} = 0, \quad (i, j, k = 1, \ldots, m - 1) \quad (23)$$

- To account for the practical situation of multiple member buckling, the cross-terms between bifurcation modes and the limit point mode satisfy:

$$\begin{align*}
V_{ijm} &\neq 0, \quad (i, j = 1, \ldots, m - 1; \ i \neq j) \quad (24) \\
V_{imm} &= 0, \quad (i = 1, \ldots, m - 1) \quad (25)
\end{align*}$$
The term for the limit point enjoys:

\[ V_{mmm} \neq 0 \]  

(26)

On the basis of (12), (13), (18) and the assumptions (25) and (26), it suffices to consider the following third-order system of the total potential energy:

\[
V = \frac{1}{2} \sum_{i=1}^{m-1} \sum_{j=1}^{m-1} V_{ijm} q_i q_j q_m + \frac{1}{6} V_{mmm} q_m^3 + \sum_{i=1}^{m} \dot{V}_i q_i \varepsilon + V'_m q_m \lambda 
\]  

(27)

Differentiating \( V \) with respect to \( q_i \) (\( i = 1, \ldots, m-1 \)) and \( q_m \) leads to

\[
\sum_{j=1}^{m-1} V_{ijm} q_j q_m + \dot{V}_i \varepsilon q_m = 0, \quad (i = 1, \ldots, m-1) 
\]  

(28)

\[
\frac{1}{2} \sum_{i=1}^{m-1} \sum_{j=1}^{m-1} V_{ijm} q_i q_j + \frac{1}{2} V_{mmm} q_m^2 + \dot{V}_m \varepsilon + V'_m \lambda = 0 
\]  

(29)

It is natural to consider an imperfection in the direction involving all the active coordinates. However, we have to investigate a special imperfection in the direction of one of the active coordinates to verify the following scaling process by \( q_m \). If \( \dot{V}_i \neq 0 \) for some \( i = 1, \ldots, m-1 \), \( q_m \neq 0 \) can be derived from (28). If \( \dot{V}_i = 0 \) for \( i = 1, \ldots, m-1 \) and \( \dot{V}_m \neq 0 \), (29) is generally satisfied by \( q_m \neq 0 \). Therefore, we can assume \( q_m \neq 0 \) in the sequel without loss of generality.

By dividing (28) by \( q_m \), we can derive

\[
\sum_{j=1}^{m-1} V_{ijm} q_j + \frac{\dot{V}_i}{q_m} \varepsilon = 0, \quad (i = 1, \ldots, m-1) 
\]  

(30)

which is to be interpreted as a set of simultaneous linear equations of \( q_j \) (\( j = 1, \ldots, m-1 \)). Since \( V_{ijm} \neq 0 \) (\( i = 1, \ldots, m-1 \)) are satisfied as the bifurcations are not degenerate (Ohsaki, 2001), \( q_j \) can be successfully found by solving (30) as

\[
q_j = \tilde{q}_j \frac{\varepsilon}{q_m}, \quad (j = 1, \ldots, m-1) 
\]  

(31)

for a set of constants \( \tilde{q}_j \) (\( j = 1, \ldots, m-1 \)). Then (30) is rewritten as

\[
\sum_{j=1}^{m-1} V_{ijm} \tilde{q}_j + \dot{V}_i = 0, \quad (i = 1, \ldots, m-1) 
\]  

(32)

With the use of (31), (29) becomes

\[
\left( \frac{1}{2} \sum_{i=1}^{m-1} \sum_{j=1}^{m-1} V_{ijm} \tilde{q}_i \tilde{q}_j \right) \frac{\varepsilon^2}{q_m^2} + \frac{1}{2} V_{mmm} q_m^2 + \dot{V}_m \varepsilon + V'_m \lambda = 0 
\]  

(33)
For each specified value of $\varepsilon$ and $\tilde{q}_i \ (i = 1, \ldots, m-1)$, the variables in (33) are considered to be $q_m$ and $\lambda$.

The condition for the critical point is written as

$$\frac{\partial \lambda}{\partial q_m} = 0 \quad (34)$$

By differentiating (33) with respect to $q_{m}$ and by using (34), we can obtain the following equation:

$$- \left( \sum_{i=1}^{m-1} \sum_{j=1}^{m-1} V_{ijm} \tilde{q}_i \tilde{q}_j \right) \frac{\varepsilon^2}{q_m^3} + V_{mmm} q_m = 0 \quad (35)$$

Eq. (35) is solved as

$$q_m^2 = \sqrt{\frac{C_m}{V_{mmm}}} |\varepsilon| \quad (36)$$

where

$$C_m = \sum_{i=1}^{m-1} \sum_{j=1}^{m-1} V_{ijm} \tilde{q}_i \tilde{q}_j \quad (37)$$

By incorporating (36) into (33), we can obtain an imperfection sensitivity law

$$\lambda = - \frac{\dot{V}_m}{V_m'} \varepsilon - \frac{1}{V_m'} \sqrt{V_{mmm} C_m} |\varepsilon| \quad (38)$$

in which $C_m$ is a function of $\tilde{q}_i$ and $\tilde{q}_j$ by (37) and, in general, cannot be expressed explicitly.

If there exist two symmetric bifurcation points at the limit point; i.e. $m = 3$, and $V_{12m} = 0$,

$$\tilde{q}_j = - \frac{\dot{V}_j}{V_{jjm}}, \quad (j = 1, 2) \quad (39)$$

is obtained from (32). Therefore, (37) is expressed explicitly and, in turn, (38) reduces to

$$\lambda = - \frac{\dot{V}_3}{V_3'} \varepsilon - \frac{1}{V_3'} \sqrt{V_{333} \left( \frac{\dot{V}_1^2}{V_{113}} + \frac{\dot{V}_2^2}{V_{223}} \right)} |\varepsilon| \quad (40)$$

which agrees with the existing result (Thompson, 1982; Ikeda et al., 2005).

A fold line has come to be employed as an alternative means to deal with imperfection sensitivity (see, e.g., Eriksson et al. (1999); Lopez and Otranto (2004). However, general properties of imperfection sensitivity can be obtained by the perturbation approach presented in this paper.
5 Numerical examples.

Consider an arch-type truss as shown in Fig. 10, where $L = 250$, $H = 200$. A load $\Lambda P$ is applied in vertical direction at the center node. The details of the analysis procedure are the same as those for the 2-bar truss in Section 2. The elastic modulus $E$ is 1 for simplicity, and $P = 0.001$. The members are divided into four groups as shown in Fig. 10. Let $A_i$ and $I_i$, respectively, denote the cross-sectional area and second-moment of area of the members in the $i$th group. The relation between $I_i$ and $A_i$ is assumed as

$$I_i = h_i^2 A_i$$  \hspace{1cm} (41)

where $h_i$ is independent of $A_i$.

Fig. 11 shows the relation between $\Lambda$ and the vertical displacement $v$ of the center node for the perfect system with $(A_1, A_2, A_3, A_4) = (100, 100, 1000, 300)$ and $(h_1, h_2, h_3, h_4) = (18.15, 18.05, 30.0, 100.0)$. A limit point is attained at $\Lambda = 4.7681$ as $\Lambda$ is increased from 0.

Fig. 12 shows the variation of the five lowest eigenvalues $e_i \ (i = 1, \ldots, 5)$ with respect to $v$. Note that $e_1$ and $e_2$ are exactly coincident, and $e_3$ and $e_4$ are nearly
Fig. 12: Relation between eigenvalues and vertical displacement of the center node.

coincident. The mode $\hat{p}_5$ corresponds to the limit-point mode. The five eigenvalues vanish simultaneously at the hill-top point.

The eigenmodes $\hat{p}_1, \ldots, \hat{p}_5$ are as shown in Fig. 13. Since a set of modes that are orthogonal with respect to the Hessian of $V$ is found by eigenvalue analysis, (25) is not usually satisfied. For example, $\hat{p}_3$ and $\hat{p}_4$ in Fig. 13 are symmetric with respect to the $y$-axis, and nodal displacements should exist to satisfy orthogonality with the limit-point mode $\hat{p}_5$, which is also symmetric. Hence $\hat{p}_3$ and $\hat{p}_4$ are the mixture of the limit point mode and the member buckling mode. $V_{333}$ does not vanish since $\hat{p}_3$ and $-\hat{p}_3$ correspond to different physical behaviors; $V_{444}$ also does not vanish. Note that $\hat{p}_1$ and $\hat{p}_2$ are antisymmetric with respect to the $y$-axis, and vertical displacements of the center node vanish; therefore, $V_{111} = V_{222} = 0$ is satisfied.

In order to distinguish limit-point mode and member buckling modes, the limit-point mode $\hat{p}_5$ is first defined as the increment of displacements at the limit point while tracing the equilibrium path by the displacement increment method. The components of $\hat{p}_5$ are subtracted from $\hat{p}_3$ and $\hat{p}_4$ to arrive at pure member buckling modes $\hat{p}_3$ and $\hat{p}_4$ shown in Fig. 14. Note that symmetric modes $\hat{p}_3$, $\hat{p}_4$ and $\hat{p}_5$ do not satisfy the orthogonality condition.

The third differential coefficients of $V$ are obtained as

$$
\begin{align*}
V_{115} &= V_{335} = -2.0842 \times 10^{-7}, \\
V_{225} &= V_{445} = -2.1415 \times 10^{-7}, \\
V_{345} &= -2.2262 \times 10^{-9}, \\
V_{555} &= -1.8214 \times 10^{-8}
\end{align*}
$$

(42)

It has been confirmed that the absolute values of the coefficients that are assumed to vanish in (23) and (25) are non-zero but are small enough compared with those in (42). Other coefficients are

$$
\begin{align*}
\dot{V}_1 &= \dot{V}_2 = -9.7979 \times 10^{-5}, \\
\dot{V}_3 &= \dot{V}_4 = -9.7963 \times 10^{-5}, \\
\dot{V}_5 &= -4.7352 \times 10^{-5}, \\
\dot{V}_5' &= -7.0748 \times 10^{-11}
\end{align*}
$$

(43)
First consider an imperfection in the direction of the sum $\varepsilon \sum_{i=1}^{5} p_i$ of five modes shown in Fig. 14. The use of (42) and (43) in (38) leads to

$$\lambda = -1.8393 \times 10^{-2} \varepsilon - 0.22176 |\varepsilon|$$

(44)

The relation between $\lambda$ and $\varepsilon$ is plotted in Fig. 15, where ‘+’ mark is the maximum load factor of an imperfect system obtained by nonlinear path-following analysis, and the solid line is the piecewise linear estimation by (44). Note that the maximum load factor of an imperfect system is attained at a limit point. It is observed from Fig. 15 that the maximum load factors of imperfect systems can be estimated with good accuracy by the linear sensitivity relation (44). Note that each member is divided into four elements, and the initial imperfection is given as a piecewise linear shape for path-following analysis of an imperfect system. On the other hand, a curved shape is assumed in computing $\dot{V}_i$. However, it has been ensured from the numerical results that discretizing errors due to the modeling stated above are negligible.

For the imperfection $\varepsilon p_5$ in the direction of limit-point mode, the second term in the right-hand-side of (44) vanishes, and the relation between $\lambda$ and $\varepsilon$ is given by a linear law

$$\lambda = -1.8393 \times 10^{-2} \varepsilon$$

(45)

which is plotted in Fig. 16.
Fig. 14: Eigenmodes corresponding to the five zero eigenvalues satisfying $V_{iii} = 0$ ($i = 1, 2, 3, 4$).

For the imperfection $\varepsilon p_1$, the first term in the right-hand-side of (44) vanishes, and the relation between $\lambda$ and $\varepsilon$ is given by a piecewise linear law

$$\lambda = -0.11134|\varepsilon|$$

which is plotted in Fig. 17. For the 3rd mode $\varepsilon p_3$, the relation is

$$\lambda = -0.11249|\varepsilon|$$

which is plotted in Fig. 18. Note that although the mode $\varepsilon p_3$ corresponds to a slightly asymmetric bifurcation, the linear term $\varepsilon$ is negligibly small.

The maximum loads have thus been accurately estimated by linear and piecewise linear relations for all the cases to assess the validity of the proposed formula (44).

6 Conclusions.

Imperfection sensitivity formulas have been developed for a hill-top branching point that has many symmetric bifurcation points at the limit point. The problem considered here is practically very important for estimating the imperfection sensitivity of interaction of global snapthrough and local member buckling. The maximum loads
Fig. 15: Relation between maximum load and imperfection parameter that include five modes.

Fig. 16: Relation between maximum load and imperfection parameter for $\varepsilon p_5$ (limit-point mode).

of imperfect systems are piecewise linear functions of imperfection parameter. Therefore, the existence of member buckling at the limit point is not dangerous in view of imperfection sensitivity. The “simultaneous mode design” for this case is not that pessimistic as was cautioned the “erosion of optimization by compound bifurcation.”
